

A practical Guide to Spreads

Translating Credit Futures Prices into Credit Spreads

Fixed Income instruments have a range of quotation convention. Bonds are usually quoted in % of par-value, either with the accrued interest included (dirty price) or not (clean price), although sometimes they are quoted in yield. For credit instruments, one core driver of the price and yield is how much more risk is priced into the bond versus a “risk-free” alternative government bond or the swap curve, also known as the Credit Spread. In particular, Credit Default Swaps mostly remove the yield curve component from the cash-flows of the bond and are often quoted in credit spread.

Eurex Credit Index futures on the other hand differ from many traditional Credit Derivatives in that they trade in units of the underlying index. These indices track the total returns of the bonds, including price returns, accrued interest and coupon returns. They grow indefinitely, and it is not immediately clear what a price means in terms of average yield of the included bonds.

A further complication arises through the market structure of bond markets. The underlying indices settle once a day, as many bonds included are not often traded and only quoted. To ensure accurate pricing, it is therefore necessary to have a longer timeframe to observe prices.

So how do we translate futures prices in traditional bond metrics like yield, or credit spread? Unfortunately, there is no exact way of calculating this, but we can still approximate with reasonable precision. There are a couple of steps involved in the process.

1. Discounting Futures prices back into cash prices by applying the fair funding rate.
2. Approximate implied yield using duration against yesterday's index print.
3. Calculate spreads against the benchmark yield.

Translating Futures Prices

Futures prices are related to cash prices with the following formula, which describes the cash-futures basis:

$$F_{t,T} = I_t * (1 + r_{t,T} - b_{t,T})^{T-t}$$

Where, I is the index value, r the fair funding rate and b the implied lending rate. If the futures are traded we have two unknown factors, I and b , as the fair funding rate is known from swap markets. Usually, two unknown factors in an equation pose a problem, as there is an infinite number of solutions. However, in this case, we can translate one into the other. A higher implied lending rate means that we can get the exposure to the underlying cheaper than funding would imply, and vice-versa. In the end, the PnL of the futures equals that of the underlying minus the basis. If b rises, then I falls, and vice versa, and the relationship is one-for-one. We can therefore assume that $b = 0$ and pull all the price information from implied lending into the underlying. The formula now reads:

$$F_{t,T} = I_t * (1 + r_{t,T})^{T-t},$$

so, the index price can be calculated using

$$I_t = F_{t,T} * (1 + r_{t,T})^{t-T}.$$

Locating Underlying Yield

Now that we have determined the index price that the futures market is implying, we still need to determine what this means in terms of yield of the constituting bonds. Following traditional bond math, bond prices may be approximated through yield using:

$$B(y) \approx \underbrace{B(y_0)}_{\text{prev close}} * \underbrace{(1 + y_0)^{1D}}_{\text{1 Day carry}} - \underbrace{D(y_0) * B(y_0) * \Delta y}_{\text{yield change}},$$

with D being the modified option adjusted duration of the bond and y_0 yesterday's closing yield to worst observed from the bond markets.

In aggregate, over the whole index, we get

$$\Delta y \approx \frac{I_{t-1} * (1 + y_0)^{1D} - I_t}{D_{I_t}}$$

Finally, we find the implied yield that is implied by the futures prices as the sum of yesterday's yield and their implied move

$$y \approx y_0 + \Delta y$$

It should be mentioned that there are quite a few shortcuts that we have taken here. The first approximation works fine as long as the yield moves are relatively constrained, as we are omitting convexity and higher order terms from the Bond price Taylor series. From a practical standpoint this should only matter when yields move more than 100bps as the convexity (usually below 1) is scaled by the square of yield move. Additionally, we omit the roll-down of bond along the curve over the period between the observation time and the previous close. This is mostly because it is difficult to establish a term structure for all bonds of the index, particularly as

some do not have a liquid credit curve. However, the impact should be fairly limited during most regimes.

Benchmarking against the curve

Credit spreads are calculated against a benchmark yield that a corresponding risk-free bond would command. But what exactly does risk-free mean? Is it the swap curve? Or rather government bonds? CDX par spreads are calculated against the swap curve, while it is common to benchmark cash bonds against the nearest German government bond or US treasuries. In the end there are multiple ways of choosing a benchmark which can differ quite substantially in terms of curve structure, liquidity in various tenors and risk factors. There are two practical methods that use Government Bond Futures:

Figure 2: Theoretical Yields of an RECMTREU Portfolio hedged with EGB Futures throughout 2024. Source: Bloomberg, Eurex.

Benchmarking against the nearest benchmark Government Bond Futures from a duration perspective.

This method is the quickest and fastest to implement. While it is generally able to track movements on the front end until the maturity of the CTD, it can lack the sensitivity on the back end. This makes this strategy particularly vulnerable to changes in the shape of the curve. The credit spread can be calculated as the spread against the yield of the CTD Bond.

Duration Window	Average Index Duration	Corresponding Hedge	Futures Duration	Futures Contracts per €100m
0-100	4.30	Bobl Future	4.36	848

Benchmarking against a portfolio of futures: One common method used by e.g. Bloomberg is to group the bonds in the underlying index into buckets, corresponding to a duration matched government bond future. The resulting portfolio of futures is able to map most curve movements accurately, and reasonably stable, so the weights don't change to much. Here, the benchmark yield is the futures price-weighted average yield of the CTDs of the hedging portfolio

Duration Window	Average Basket Duration	Corresponding Hedge	Futures Duration	Futures Contracts per €100m
0-2.5	1.69	Schatz Future	1.82	245
2.5-7	4.45	Bobl Future	4.36	513
7-13	8.56	Bund Future	7.92	97
13-100	15.51	Buxl Future	19.96	7
